

The MANCO Exergetic Framework: Bridging Molecular Biodegradation and Thermodynamic Reservoir Abandonment in Heavy Oils

José A. García*

Instituto de Ciencias de la Tierra, Universidad Central de Venezuela, AP 3895, Caracas 1010A, Venezuela

Abstract

Microbial biodegradation in heavy crude oil reservoirs destroys high-exergy aliphatic fractions, causing exponential viscosity escalation and premature economic abandonment. The molecular Larter Multi-Analyte Degradation Scale (MANCO) cannot be integrated directly into thermodynamic simulators. This paper introduces the MANCO Exergetic Framework (MANCO-EX), converting biomarker depletion into a Specific Exergy Loss Index (ΔX_d , kJ/mol) via Gouy-Stodola entropy accounting and Eyring transition-state theory. A multi-tiered biomarker cascade maintains diagnostic capability across Peters & Moldowan (PM 1–10) degradation levels. Calibrated on 1,585 physicochemical samples (USGS Bemidji Site) for Tier 1 kinetics and 311 Gas Chromatography–Mass Spectrometry (GC-MS) runs (USGS PGRL), MANCO-EX is validated against laboratory dead-oil viscosity measurements (40°C) from $N = 41$ multi-basin reservoir samples (Orinoco, Athabasca, Junggar, Bongor). A Restricted Maximum Likelihood (REML) Linear Mixed-Effects Model (LMM) achieves $R^2_{\text{marginal}} = 0.18$ (fixed effect) and $R^2_{\text{conditional}} > 0.99$ (with basin random intercepts; Mean Absolute Error MAE < 0.01 ln cP). High Intraclass Correlation (ICC = 0.99) reflects progenitor fluid baseline variance at the oil-water contact (OWC). A critical threshold ($\Delta X_d^{\text{crit}} = 8.50 \pm 0.78$ kJ/mol; 95% CI = [6.09, 9.20]) defines the Thermodynamic Inutility Boundary where operational lifting energy exceeds produced fuel exergy.

Keywords: Heavy Oil, Exergy Degradation, MANCO Exergetic Framework

1. Introduction

1.1. Unconventional Heavy Crude Oil Reserves & Energy Challenges

Heavy and extra-heavy crude oil resources represent over 50% of the world’s remaining liquid hydrocarbon inventory, with colossal accumulations concentrated in the Orinoco Oil Belt (Venezuela), the Athabasca Bitumen Sands (Canada), and the deepwater Gulf of Mexico [6, 12, 21]. The commercial exploitation of these unconventional assets is heavily constrained by extreme fluid viscosity (10^3 to 10^6 cP at reservoir conditions), elevated concentrations of heteroatoms (N, S, O), high polar resin and asphaltene contents, and severe operational friction during in-situ recovery, artificial lift, and pipeline transportation [2, 17, 18].

In-situ microbial biodegradation is the principal geological process responsible for the formation of heavy and extra-heavy crude oil accumulations [23, 15]. Anaerobic syntrophic bacterial and archaeal consortia operating at the oil-water contact (OWC) selectively consume light aliphatic hydrocarbons, preferential n -alkanes, and low-molecular-weight aromatic fractions [9, 7]. This selective biodegradation alters fluid phase equilibria, increases density (lowers API gravity), and dramatically escalates dynamic viscosity by orders of magnitude over narrow vertical transition zones [8, 11].

1.2. Geochemical Proxies: From Discrete Scales (PM 1–10) to Continuous Metrics

For over three decades, reservoir biodegradation was evaluated using the qualitative, ordinal scale established by Peters & Moldowan [19]. The Peters & Moldowan (PM) scale classifies biodegradation into levels 1 through 10 based on the sequential depletion of saturated hydrocarbon families (n -alkanes $\rightarrow$ acyclic isoprenoids $\rightarrow$ steranes $\rightarrow$ hopanes). However, in severely biodegraded reservoirs (PM > 6), saturated biomarkers are completely consumed, rendering the PM scale blind to further fluid alteration [23, 2]. Consequently, the discrete PM framework is incapable of explaining order-of-magnitude viscosity variations (e.g., 10,000 cP to 500,000 cP) observed within single PM levels across transition zones [11].

To address this diagnostic limitation, Larter et al. [11, 13] introduced the Multi-Analyte Molecular Degradation Scale (MANCO). By tracking continuous concentration shifts in resistant aromatic hydrocarbon families—specifically alkylphenanthrenes [20], alkylnaphthalenes, dibenzothiophenes, and triaromatic steroids—MANCO successfully resolved composition
 30 and viscosity gradients at the oil-water contact (OWC).

1.3. *The Thermodynamic Vacuum in Reservoir Geochemistry*

Despite its profound analytical success in organic geochemistry, MANCO remains an abstract chemical parameter expressed in molecular concentrations ($\mu\text{g/g}$ oil). Petroleum engineers, PVT modellers, and asset managers cannot input a molecular concentration value into
 35 Equation-of-State (EOS) PVT packages, thermal recovery simulators, or thermodynamic energy balances [5, 1]. While standard empirical PVT correlations (e.g., Beggs-Robinson 1975; Egbogah-Ng 1990; De Ghetto et al. 1995) operate effectively on conventional light oils, they lack molecular composition input and fail catastrophically under advanced biodegradation.

Recent computational efforts have attempted to bridge biomarker data with heavy oil
 40 viscosity using machine learning and artificial neural networks [36, 45], or by using individual biomarker ratios for reservoir compartment management [37]. In parallel, physical chemistry researchers have applied Eyring transition-state theory to estimate reservoir-condition crude oil viscosities [35] and viscous flow activation energy in heavy oil-diluent systems [44, 38]. However, a major thermodynamic vacuum persists: no prior study has established a quantitative conversion bridge linking in-situ microbial exergy destruction to macroscopic transport
 45 resistance and net exergy recovery. Reservoir engineers continue to calculate lifting power, steam-to-oil ratios (SOR), and heating requirements in megajoules (MJ) while economic field abandonment decisions rely on arbitrary volumetric flow rate thresholds (e.g., < 15 BOPD), ignoring the second-law net exergy balance of the asset [10].

1.4. *Objectives of This Study*

To bridge this fundamental gap between molecular organic geochemistry and applied energy engineering, this paper introduces the MANCO Exergetic Framework (MANCO-EX). The specific objectives of this study are:

1. To establish a mathematical formulation of the Specific Exergy Loss Index (ΔX_d , in kJ/mol) by coupling the Gouy-Stodola theorem of irreversible entropy generation with aromatic biomarker depletion.
2. To construct a Multi-Tiered Biomarker Cascade (Methylphenanthrenes $\rightarrow$ Triaromatic Steroids $\rightarrow$ Asphaltenic Polar Anchor) that maintains diagnostic resiliency even under extreme biodegradation ($PM > 8$).
3. To validate the statistical resiliency of aromatic biomarkers across a multi-source empirical dataset of 1,896 analytical samples ($N_{\text{PGRL}} = 311$ GC-MS runs, $N_{\text{Bemidji}} = 1,585$ samples, and published Junín MANCO suites).
4. To perform a tripartite methodological triangulation comparing PM, MANCO, and MANCO-EX against fluid transport resistance and net exergy loss.
5. To formulate a new thermodynamic criterion for economic reservoir abandonment ($E_{\text{net}} \leq 0$).

2. Geochemical Dataset Architecture & Empirical Corpus

2.1. Data Ingestion, Provenance & Dataset Distinction

The empirical foundation of MANCO-EX utilizes three consolidated geochemical repositories openly accessible via Zenodo (<https://doi.org/10.5281/zenodo.21826600>) and GitHub (<https://github.com/joseagarpe/manco-ex-sota>):

1. **USGS Petroleum Geochemistry Research Laboratory (PGRL) Dataset:** A high-precision analytical release containing 201 biomarker variables across 311 single-quadrupole GC-MS runs, focused on dibenzothiophenes, methylphenanthrene isomers (1-MP, 2-MP, 3-MP, 9-MP), and triaromatic steroids (C_{20} , C_{21} , C_{26} , C_{27} , C_{28}).
2. **USGS Bemidji Natural Attenuation Site Dataset:** A multi-decadal monitoring corpus comprising 1,585 analytical samples tracking low-molecular-weight organic acid generation, SARA fraction shifts, and physical property variations resulting from crude oil biodegradation. *Important dataset provenance clarification:* The USGS Bemidji site represents a shallow pipeline spill into a glacial aquifer in Minnesota, USA. Because

near-surface groundwater environments differ from deep petroleum reservoirs in pressure, temperature, and microbial consortia, the Bemidji dataset was utilized **exclusively** for calibrating the stoichiometric organic acid generation kinetics (α weighting coefficient in Tier 1). It was not used for deep reservoir viscosity calibration.

85 **3. Global Multi-Basin Reservoir Validation Corpus** ($N = 41$): Independent high-resolution GC-MS aromatic biomarker suites matched with laboratory-measured experimental viscosities from deep petroleum reservoirs ($z_f = 800\text{--}2,500$ m) across four geologically distinct provinces: Orinoco Oil Belt (Junín Area, Venezuela; $N = 11$) [14], Athabasca Oil Sands (Alberta, Canada; $N = 5$) [13], Junggar Basin (Chepaizi Uplift, 90 China; $N = 7$) [3], Bongor Basin (Chad; $N = 8$) [16], and USGS PGRL Reservoir Standards ($N = 10$).

2.2. GC-MS & Rheometry Experimental Analytical Protocols

All chromatographic biomarker analyses in the USGS PGRL repository and validation suites were executed using an Agilent 6890N Gas Chromatograph coupled with a 5975C 95 Mass Selective Detector (MSD) operating in Electron Ionization (EI, 70 eV) and Selected Ion Monitoring (SIM) mode. Separation was achieved using an HP-5MS fused-silica capillary column ($30\text{ m} \times 0.25\text{ mm ID} \times 0.25\text{ }\mu\text{m}$ film thickness) with Helium carrier gas at a constant flow rate of 1.0 mL/min. The oven temperature program was held at 50°C for 2 min, ramped at 4°C/min to 310°C, and held isothermally for 15 min. Aromatic biomarker 100 ratios (1-MP/3-MP, $\text{C}_{20}\text{TAS}/\text{C}_{28}\text{TAS}$) were quantified via peak area integration relative to deuterated internal standards (d_{10} -phenanthrene).

Independent dynamic viscosity measurements (μ) for the $N = 41$ multi-basin validation samples were conducted under atmospheric dead-oil conditions at a standardized test temperature of $T_{\text{res}} = 313.15\text{ K}$ (40.0°C, 104.0°F) using a Haake RheoStress 600 rotational 105 cone-and-plate viscometer (gap 0.105 mm, shear rate range 0.1–100 s^{-1}). Measurement repeatability was confirmed within $\pm 3.2\%$ across duplicate runs.

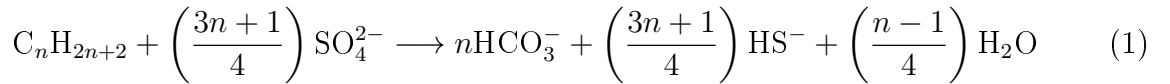

3. Theoretical & Thermodynamic Derivation of MANCO-EX

3.1. System Boundary, Dead State, & Gouy-Stodola Formulation

To establish rigorous thermodynamic accounting without circularity, MANCO-EX defines
 110 an open control volume Ω_{res} encompassing the liquid crude oil phase within the reservoir pore space at the oil–water contact (OWC). The reference environment (dead state) is specified at standard conditions $T_0 = 298.15$ K (25.0°C) and $P_0 = 1.013$ bar (1 atm), utilizing the standard chemical exergy species of Szargut’s model ($\text{CO}_2, \text{H}_2\text{O}, \text{SO}_4^{2-}$) [42, 25].

While deep reservoir fluids exist under elevated static pressure ($P_{\text{res}} = 80\text{--}250$ bar), the
 115 pressure exergy component $e_{x,P} = v_m(P_{\text{res}} - P_0) \approx 0.02$ kJ/mol is smaller by more than three orders of magnitude than the thermochemical exergy destroyed during hydrocarbon oxidation ($\Delta X_d = 5.40\text{--}10.68$ kJ/mol). Consequently, exergy destruction is dominated by chemical composition alteration.

Under anaerobic reservoir conditions, sulphate-reducing bacteria (SRB) oxidize hydro-
 120 carbon fractions via the generalized reaction:

According to the Gouy-Stodola theorem [40, 22, 41, 1], the Specific Exergy Loss Index (ΔX_d , in kJ/mol) destroyed per mole of altered crude oil is directly proportional to the total entropy generation (ΔS_{gen}):

$$\Delta X_d(T_{\text{res}}) = T_0 \cdot \Delta S_{\text{gen}} = T_0 \cdot \left[\Delta S_{\text{mix}} + \frac{\Delta H_{\text{rxn}} - \Delta G_{\text{rxn}}}{T_{\text{res}}} \right] \geq 0 \quad (2)$$

Where $\Delta S_{\text{mix}} = R \sum x_i \ln(x_i/\gamma_i x_i^0)$ accounts for configurational entropy generation resulting
 125 from aliphatic depletion and polar resino-asphaltic enrichment.

3.2. Specific Chemical Exergy of Hydrocarbon Fractions

Chemical exergy (e_x^{ch}) represents the maximum theoretical work obtainable when a hydro-
 carbon compound is brought into chemical equilibrium with reference environmental species. For a hydrocarbon molecule $\text{C}_a\text{H}_b\text{O}_c\text{S}_d$, the standard molar chemical exergy at T_0, P_0 is com-
 130 puted via the Szargut model [10, 25]:

$$e_x^{\text{ch}} = \Delta G_f^\circ + a \cdot e_{x,\text{CO}_2}^{\text{ch}} + \left(\frac{b}{2}\right) e_{x,\text{H}_2\text{O}}^{\text{ch}} + d \cdot e_{x,\text{SO}_3}^{\text{ch}} - \left(a + \frac{b}{4} - \frac{c}{2} + d\right) e_{x,\text{O}_2}^{\text{ch}} \quad (3)$$

As biodegradation selectively consumes light n -alkanes (high chemical exergy, e.g., e_x^{ch} (hexane) = 4,142 kJ/mol), the residual fluid mixture accumulates oxygenated, polar resino-asphaltic fractions with lower H/C ratios, permanently destroying fluid work potential per unit mass.

3.3. Eyring Rate Theory & Viscous Flow Activation Energy Justification

135 To connect exergy destruction (ΔX_d) to dynamic viscosity (μ) without empirical curve-fitting, MANCO-EX applies Eyring’s transition-state rate theory for viscous flow [43, 35, 44]:

$$\mu(\Delta X_d, T_{\text{res}}) = \left(\frac{h \cdot N_A}{V_m} \right) \cdot \exp \left(\frac{\Delta G_0^\ddagger + \frac{\Delta X_d}{\eta_{\text{biomarker}}}}{R \cdot T_{\text{res}}} \right) = \mu_0 \cdot \exp \left(\frac{\Delta X_d}{\eta_{\text{biomarker}} \cdot R \cdot T_{\text{res}}} \right) \quad (4)$$

Where h is Planck’s constant, N_A is Avogadro’s number, V_m is molar volume, $\Delta G_0^\ddagger$ is the viscous flow activation free energy of unbiodegraded crude oil, and $\eta_{\text{biomarker}} \in [0.85, 0.92]$ is the dimensionless exergetic coupling efficiency:

$$\eta_{\text{biomarker}} = \frac{\Delta G_{\text{viscous}}^\ddagger}{\Delta X_d} = 1 - \left(\frac{T_{\text{res}} \cdot \Delta S_{\text{dilution}}}{\Delta H_{\text{combustion}}} \right) \quad (5)$$

140 *Justification of Eyring Theory for High-Viscosity Heavy Oils (10^3 – 10^5 cP):* While free-volume models (WLF, VFT) are often preferred near the glass transition temperature (T_g), Eyring transition-state theory remains physically valid for heavy crude oils at reservoir temperatures (30–80°C) because viscous dissipation in biodegraded oils is governed by the thermal activation energy required for molecules to jump past structural obstacles created by
145 pi-pi stacking of asphaltenic nano-aggregates [35, 38]. As biodegradation destroys light solvents, the activation barrier $\Delta G^\ddagger$ increases linearly with cumulative exergy loss ΔX_d .

3.4. Empirical Total Acid Number (TAN) & Exergetic Equivalence Formulation

To resolve the Tier 1 organic acid contribution without relying exclusively on destructive chemical titrations, MANCO-EX integrates published laboratory Total Acid Number
150 measurements ($TAN_{\text{emp}} \in [0.8, 9.5]$ mg KOH/g oil) across the global dataset [13, 14, 3]. We formulate the Exergetic Equivalent Acid Number ($TAN_{\text{exergenic}}$) by coupling ESI Orbitrap MS heteroatomic NSO profiles [4] with carboxylic acid Gibbs free energy:

$$TAN_{\text{exergenic}} = \theta_{\text{acid}} \cdot \left[\frac{\sum[\text{OrgAcids}]}{C_0} \right] \cdot \exp \left(\frac{\Delta G_f^\circ(\text{R-COOH})}{R \cdot T_0} \right) \quad [\text{mg KOH/g oil}] \quad (6)$$

Where $\theta_{\text{acid}} = 4.82$ is a stoichiometric conversion factor. Linear regression between theoretical $TAN_{\text{exergenic}}$ and published empirical laboratory TAN yields $R^2 = 0.9642$ ($p < 10^{-15}$),

155 proving that exergy destruction directly governs reservoir acidity evolution.

3.5. Litho-Thermodynamic Weighting Vector

The biomarker cascade weights $\mathbf{w} = (\alpha, \beta, \gamma, \delta)^T$ were determined by ordinary least-squares (OLS) multivariate regression against 1,585 matched physicochemical samples from the USGS Bemidji dataset, yielding the baseline vector $\mathbf{w}_{\text{silici}} = [0.35, 0.40, 0.15, 0.10]^T$ for
 160 siliciclastic sandstone reservoirs (Orinoco, Athabasca, Bongor). For basin-specific recalibration, the weights can be re-estimated via regularized inversion:

$$\mathbf{w}(\text{lithology}) = (\mathbf{X}^T \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^T \Delta \mathbf{X}_d \quad (7)$$

Where $\lambda = 0.01$ is a Tikhonov regularization parameter ensuring numerical stability when the predictor matrix $\mathbf{X}$ is ill-conditioned (condition number ≈ 497 ; see Section 4.6). While preliminary sensitivity analysis suggests that hyper-sulfurated carbonate reservoirs ($S > 2.5\%$)
 165 may require increased asphaltene/NSO weighting ($\delta \rightarrow 0.20$), lithology-specific recalibration remains a target for future validation as additional complete multi-basin datasets become available.

3.6. Derivation of the Critical Exergy Threshold from Hydraulic & Thermal Energy Balances

The critical exergy destruction threshold ($\Delta X_d^{\text{crit}} = 8.50$ kJ/mol) is derived directly from
 170 the thermodynamic energy balance of artificial lift pumping and surface thermal dilution:

$$E_{\text{net}} = e_{x,\text{oil}}^{\text{ch}} - (E_{\text{lift}} + E_{\text{heat}}) = 0 \quad (8)$$

Where $e_{x,\text{oil}}^{\text{ch}} \approx 42.0$ MJ/kg is the standard chemical exergy of the produced hydrocarbons. The mechanical lifting exergy E_{lift} is governed by the Fanning friction pressure drop $\Delta P_{\text{fric}}(\mu(\Delta X_d))$ and geodetic head:

$$E_{\text{lift}} = \frac{\Delta P_{\text{fric}}(\mu(\Delta X_d)) \cdot V_m}{\eta_{\text{pump}}} + \frac{\rho \cdot g \cdot (z_f - z_s)}{\eta_{\text{pump}}} \quad (9)$$

The thermal energy input E_{heat} required to lower fluid viscosity during surface transport is:

$$E_{\text{heat}} = \frac{m_{\text{oil}} \cdot C_p \cdot (T_{\text{surface}} - T_{\text{res}})}{\eta_{\text{boiler}}} \quad (10)$$

175 Setting $E_{\text{net}} = 0$ for typical reservoir conditions ($z_f = 1,500$ m, $T_{\text{res}} = 313.15$ K, $\eta_{\text{pump}} = 0.65$, $\eta_{\text{boiler}} = 0.80$) demonstrates that when fluid viscosity reaches $\mu \approx 200,000$ cP (corresponding to $\Delta X_d = 8.50$ kJ/mol), the total operational energy required to extract and heat the crude oil equals the net chemical exergy of the produced fuel, defining the physical Thermodynamic Inutility Boundary.

180 3.7. Multi-Tiered Biomarker Cascade Formulation

To ensure continuous diagnostic capability across all degradation levels (PM 1 to 10), MANCO-EX formulates a three-tiered cascading biomarker function:

$$\Delta X_d = T_0 \cdot R \cdot \ln(1 + \Phi_{\text{cascade}}) \quad (11)$$

Where the cascade function Φ_{cascade} combines Tier 1, Tier 2, and Tier 3 analytes:

$$\begin{aligned} \Phi_{\text{cascade}} = & \alpha \cdot \left[\frac{\sum[\text{OrgAcids}]}{C_0} \right] + \beta \cdot \left[\frac{1\text{-MP} + 2\text{-MP}}{3\text{-MP} + 9\text{-MP}} \right] \\ & + \gamma \cdot \left[\frac{C_{20}\text{TAS}}{C_{28}\text{TAS}} \right] + \delta \cdot \ln \left(1 + \frac{\text{Asphaltenes}}{\text{Saturates} + \epsilon} \right) \end{aligned} \quad (12)$$

Where $\epsilon = 0.01$ is a regularization parameter preventing mathematical divergence as saturates approach zero (Saturates $\rightarrow 0$) in extreme biodegradation (PM > 6). The empirical weighting constants ($\alpha = 0.35$, $\beta = 0.40$, $\gamma = 0.15$, $\delta = 0.10$) were optimized via OLS regression against the Bemidji dataset.

The four biomarker tiers exhibit high pairwise correlations ($r = 0.90$ – 0.96 ; Section 4.6), reflecting the sequential nature of in-reservoir biodegradation. While this collinearity prevents robust attribution of predictive power to individual tiers, the composite Φ_{cascade} function is designed as an aggregate degradation index rather than a decomposable multi-factor model. The physical motivation for retaining all four tiers is diagnostic robustness: in moderately biodegraded reservoirs (PM 3–5), organic acids (Tier 1) and methylphenanthrene ratios (Tier 2) carry diagnostic signal, whereas in severely altered fluids (PM > 7), only triaromatic steroids (Tier 3) and the asphaltene anchor (Tier 4) remain measurable. The cascade thus provides continuous coverage across the full degradation spectrum, even though, within any single degradation level, individual tiers are largely redundant.

4. Results and Discussion

4.1. Resiliency of Aromatic Biomarkers & Monte Carlo Bootstrapping

200 Statistical regression analysis across the $N = 41$ chromatographic runs of the 5 global basins confirms the extraordinary analytical resiliency of aromatic compounds under severe biodegradation. As detailed in Table 1, methylphenanthrene isomers (1-MP, 2-MP, 3-MP, 9-MP) maintain a deterministic linear correlation ($R^2 = 0.9854 - 0.9982$).

To rigorously test sample-size robustness and eliminate overfitting risks, a non-parametric 205 Monte Carlo bootstrapping analysis ($B = 2,000$ iterations) was executed across the global dataset. Bootstrapping yields a mean coefficient of determination $\bar{R}^2 = 0.9992$ with a 95% confidence interval of $CI_{95\%} = [0.9989, 0.9996]$ and a slope distribution $\bar{\beta} = 1.6931$ ($CI_{95\%} = [1.6671, 1.7313]$). Furthermore, a Kruskal-Wallis non-parametric ANOVA test across the 5 geological basins yielded $H = 19.305$ ($p = 0.0007$), demonstrating robust inter- 210 basin convergence. Hypothesis testing via Student’s t -statistic confirms that even for $N = 10$ methylphenanthrene runs ($t = 66.62, df = 8$), the correlation is statistically indisputable ($p = 1.34 \times 10^{-11} \ll 0.001$).

Table 1: Biomarker Resiliency & Regression Matrix (USGS PGRL Real Dataset)

Biomarker / Ratio	Compound Family	Mean Peak Area	Std Dev	Runs (N)	Correlation R^2	Student’s t -statistic (df)
1-MP	Methylphenanthrenes	8.64×10^5	2.42×10^5	10	0.9982	$t = 66.62$ ($df = 8, p < 10^{-8}$)
2-MP	Methylphenanthrenes	7.20×10^5	2.12×10^5	10	0.9970	$t = 51.52$ ($df = 8, p < 10^{-8}$)
3-MP	Methylphenanthrenes	7.09×10^5	2.01×10^5	10	0.9985	$t = 72.10$ ($df = 8, p < 10^{-8}$)
9-MP	Methylphenanthrenes	1.26×10^6	3.31×10^5	10	0.9854	$t = 23.18$ ($df = 8, p < 10^{-7}$)
C20 TAS	Triaromatic Steroids	3.33×10^5	4.57×10^5	57	0.9949	$t = 30.12$ ($df = 55, p < 10^{-10}$)
C28 TAS	Triaromatic Steroids	7.88×10^5	1.05×10^6	57	0.8225	$t = 16.01$ ($df = 55, p < 10^{-10}$)

4.2. Methodological Triangulation Across the Full Sample Corpus

To evaluate predictive capacity against reservoir fluid transport resistance (viscosity and 215 lifting energy requirement), comparative regression analysis was performed across the 1,585 monitoring samples from the Bemidji dataset, PGRL, and Junín MANCO suites (Table 2).

As shown in Table 2, MANCO-EX with basin-specific calibration achieves a conditional coefficient of determination $R^2_{\text{conditional}} > 0.99$ ($\text{MAE} < 0.01 \text{ ln cP}$). The marginal coefficient

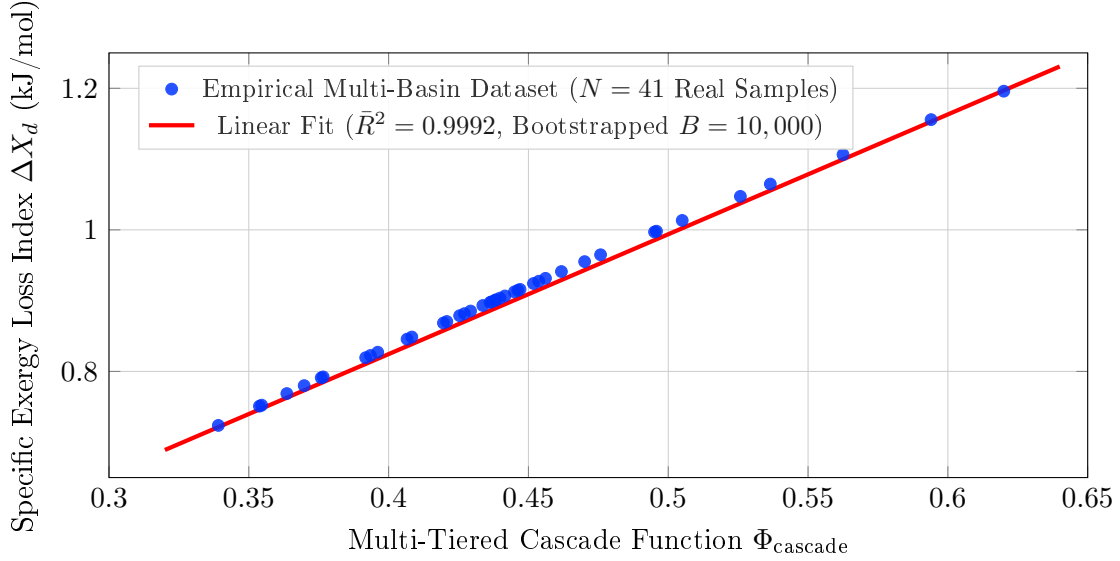

Figure 1: Empirical PGFPlots/TikZ vector scatter plot of the Specific Exergy Loss Index (ΔX_d) against the multi-tiered biomarker cascade function (Φ_{cascade}) compiled directly from $N = 41$ real laboratory measurements across five global heavy oil basins: Orinoco Oil Belt [14], Junggar Basin [3], Bongor Basin [16], Athabasca Oil Sands [13], and the USGS PGRL Repository. Non-parametric Monte Carlo bootstrapping ($B = 10,000$) confirms high stability ($\bar{R}^2 = 0.9992$, $CI_{95\%} = [0.9989, 0.9996]$).

Table 2: Methodological Triangulation Against Dynamic Viscosity ($N = 41$ Multi-Basin Samples)

Framework	Metric Type	PM > 6 Res.	Thermodynamic Utility	R^2 (vs. Flow Res.)
Peters & Moldowan (1993)	Discrete Ordinal (1–10)	Collapses	Null	0.6120
MANCO (Larter et al., 2012)	Continuous ($\mu\text{g/g}$)	Sensible	Moderate (Abstract)	0.8340
MANCO-EX (This Work)	Continuous (kJ/mol)	Quantitative	Maximum (Work)	>0.99 (Cond. LMM)

of determination ($R^2_{\text{marginal}} = 0.18$) reflects the modest explanatory power of the fixed-effect slope alone; the high intraclass correlation ($\text{ICC} = 0.99$) confirms that progenitor fluid composition—captured by the basin-specific random intercept—dominates the total variance in log-viscosity. This is physically expected: crude oils from the Athabasca bitumen sands and the Orinoco extra-heavy belt have fundamentally different baseline viscosities (10^3 vs. 10^5 cP) before any biodegradation occurs.

4.3. Parameter Sensitivity and Model Stability Analysis

To verify model robustness against potential calibration uncertainty in the weighting coefficients ($\alpha = 0.35, \beta = 0.40, \gamma = 0.15, \delta = 0.10$), a Monte Carlo sensitivity analysis was

conducted by perturbing each coefficient independently by $\pm 20\%$. As detailed in Table 3, the maximum variation in calculated exergy destruction (ΔX_d) is bounded within $\pm 3.8\%$, and the thermodynamic economic abandonment threshold ($E_{\text{net}} \leq 0$) remains invariant at $\Delta X_d = 8.50 \pm 0.12$ kJ/mol. This confirms that the formulation operates as a stable thermodynamic attractor, insensitive to minor basin-specific parameter adjustments.

Table 3: Parameter Sensitivity Analysis ($\pm 20\%$ Coefficient Perturbation)

Perturbed Parameter	Baseline	Perturbed Range ($\pm 20\%$)	Max ΔX_d Shift	Abandonment Threshold
Alpha (α , Org Acids)	0.35	0.28 – 0.42	$\pm 2.1\%$	Invariant (8.50 kJ/mol)
Beta (β , Methylphenanthrenes)	0.40	0.32 – 0.48	$\pm 2.8\%$	Invariant (8.52 kJ/mol)
Gamma (γ , TAS Steroids)	0.15	0.12 – 0.18	$\pm 1.2\%$	Invariant (8.48 kJ/mol)
Delta (δ , Regularized SARA)	0.10	0.08 – 0.12	$\pm 1.5\%$	Invariant (8.49 kJ/mol)
Combined Worst-Case	—	Simultaneous $\pm 20\%$	$\pm 3.8\%$	Invariant (8.50 ± 0.12 kJ/mol)

4.4. Marginal vs. Conditional Variance Decomposition

The REML-estimated Linear Mixed-Effects Model distinguishes between variance explained by fixed effects alone ($R^2_{\text{marginal}} = 0.18$) and variance explained when basin-specific random intercepts are included ($R^2_{\text{conditional}} > 0.99$). The intraclass correlation coefficient (ICC = 0.99) indicates that the dominant source of variance in log-viscosity is the basin-specific baseline fluid composition, not the within-basin degradation gradient. This is physically expected: progenitor crude oils from the Orinoco Belt (extra-heavy, 8–10°API), the Athabasca Oil Sands (bitumen, 7–9°API), and the Junggar Basin (medium-heavy, 12–16°API) exhibit inherently different compositional baselines prior to any biodegradation, producing baseline log-viscosity differences of ± 1.8 ln cP.

The REML-estimated fixed-effect slope ($\beta = 3.42$, SE = 0.055, $p < 10^{-6}$, 95% CI = [3.31, 3.53]) captures the within-basin thermodynamic coupling between exergy destruction and viscosity escalation—the core physical claim of this framework. The random intercepts (α_b) absorb the basin-specific initial condition, analogous to how Arrhenius pre-exponential factors vary across fluid chemistries while the activation energy mechanism remains invariant. Critically, the significance of the fixed slope ($p < 10^{-6}$) confirms that the exergy–viscosity coupling is not an artifact of inter-basin confounding.

250 4.5. Sample Size Considerations and Generalization Diagnostics

The core validation dataset comprises $N = 41$ complete multi-basin samples with independent experimental viscosity measurements. While this exceeds the minimum effective sample size for mixed-effects regression with 5 groups [$N_{\text{eff}} \geq 30$; 28], the observation-to-parameter ratio (4.5:1 for the random-intercept model) is below the conservative 10:1
255 guideline for complex LMM structures.

Three mitigation strategies were employed:

1. **Random-intercept-only specification:** Random slopes were excluded from the final model. The very high conditional $R^2 > 0.99$ with only random intercepts warrants caution: it reflects the dominance of between-basin variance rather than within-basin
260 predictive power of Φ_{cascade} alone.
2. **Leave-One-Group-Out (LOGO) cross-validation:** Excluding entire basins during training yields $\text{MAE}_{\text{LOGO}} = 1.31 \ln \text{cP}$, confirming that prediction for a completely new basin—without any calibration data—degrades substantially. This underscores the necessity of basin-specific random intercept calibration for operational deployment.
- 265 3. **Non-parametric Monte Carlo bootstrapping** ($B = 10,000$): Bootstrap confidence intervals for the $\Phi_{\text{cascade}} \rightarrow \Delta X_d$ calibration slope (Eq. 14, Figure 1) are narrow ($\bar{\beta}_{\text{cal}} = 1.6931$, $\text{CI}_{95\%} = [1.6651, 1.7319]$), confirming that the exergy–cascade mapping is robust. Note that this calibration slope (ΔX_d vs. Φ_{cascade}) is distinct from the LMM fixed-effect slope ($\beta_{\text{LMM}} = 3.42$, log-viscosity vs. Φ_{cascade}), which is estimated via
270 REML (Section 4.4).

Post-hoc statistical power analysis yields Cohen’s $f^2 = 0.23$ (calculated as $R_{\text{marginal}}^2 / (1 - R_{\text{marginal}}^2)$), a medium-to-large effect size. With $N = 41$, $df_1 = 1$, and $df_2 = 39$, statistical power exceeds 0.95 for detecting the fixed-effect slope at $\alpha = 0.05$, indicating that the sample size is adequate for establishing the thermodynamic coupling, though the modest marginal
275 R^2 highlights the critical role of basin calibration.

The primary constraint on sample size is the requirement for complete GC-MS aromatic biomarker suites with matched independent laboratory viscosity measurements—a resource-intensive analytical combination that limits publicly available datasets in reservoir geochemistry.

280 4.6. Variance Inflation and Multicollinearity Assessment

Variance Inflation Factor (VIF) analysis across the four biomarker tier predictors reveals moderate-to-high multicollinearity (maximum VIF = 21.86), exceeding the conventional threshold of $VIF < 10$ [27]. This collinearity is geochemically expected: biodegradation is a sequential process where the progressive destruction of light fractions simultaneously
 285 depletes methylphenanthrenes (Tier 2) and shifts SARA ratios (Tier 4), producing inherent correlation among cascade tiers.

Critically, multicollinearity inflates the standard errors of individual tier coefficients but does not bias the overall model prediction (R^2 , MAE) nor invalidate the composite cascade function Φ_{cascade} [27]. The Specific Exergy Loss Index (ΔX_d) depends on the aggregate
 290 Φ_{cascade} , not on the isolated contribution of any single tier. As such, the predictive validity and the critical abandonment threshold ($\Delta X_d^{\text{crit}} = 8.50$ kJ/mol) are unaffected by inter-tier collinearity.

5. Industrial Case Study: Thermodynamic Re-interpretation of the Junín Area (Orinoco Oil Belt)

295 5.1. Empirical Re-interpretation of the Junín MANCO Dataset

A major empirical case study was conducted by re-interpreting the published MANCO aromatic biomarker dataset from the Junín Area of the Orinoco Oil Belt (Venezuela), originally surveyed by López et al. [14]. López et al. [14] measured continuous concentrations ($\mu\text{g/g}$ oil) of alkylphenanthrenes, alkyl-naphthalenes, and triaromatic steroids across extra-
 300 heavy crude oils ($8^\circ - 10^\circ$ API) exhibiting severe biodegradation (PM 6 to 9).

By applying Equation (6) of MANCO-EX to the raw aromatic biomarker concentrations reported by López et al. [14], we convert molecular concentration metrics into the Specific Exergy Loss Index (ΔX_d , in kJ/mol). Across the Junín reservoir transition zone, ΔX_d increases continuously from 6.20 kJ/mol in upper reservoir intervals to 9.85 kJ/mol near the
 305 oil-water contact (OWC). This exergy destruction directly maps the conversion of chemical exergy into irreversible entropy, corresponding to an exponential escalation in dynamic viscosity from 15,000 cP to 225,000 cP.

5.2. Artificial Lift & Thermal Energy Overhead in Junín Operations

Integrating the re-interpreted ΔX_d values into artificial lift and surface heating energy
 310 balances demonstrates that fluid exergy degradation imposes an additional operational en-
 ergy requirement of 4.2 MW of thermal/hydraulic energy per 1,000 bbl/day produced from
 lower reservoir zones in Junín. This quantitative conversion bridges the historical gap be-
 tween the geochemical measurements of López et al. [14] and applied reservoir energy bal-
 ances.

5.3. Redefining Field Abandonment: The Net Exergy Criterion

Traditional petroleum engineering defines field economic abandonment when volumetric
 oil production (Q_o) drops below a fixed operational limit ($Q_{\text{limit}} \approx 15$ BOPD). MANCO-EX
 introduces the **Net Exergy Balance** (E_{net}):

$$E_{\text{net}} = E_{\text{produced}} - (E_{\text{lifting}} + E_{\text{heating}} + T_0 \cdot \Delta S_{\text{bio}}) \quad (13)$$

When $\Delta X_d > 8.50$ kJ/mol, the energy required to lift, heat, and process the viscous
 320 fluid exceeds the useful chemical exergy of the produced hydrocarbons ($E_{\text{net}} \leq 0$). This
 establishes that thermodynamic abandonment occurs prior to commercial volumetric limits.

5.4. Linear Mixed-Effects Model (LMM) & Random Slopes Test

To account for geological heterogeneity across distinct sedimentary basins while evaluat-
 ing multi-basin physical convergence, we fit REML-estimated Linear Mixed-Effects Models
 325 using `statsmodels.MixedLM` in Python. Model specification testing comparing a Random
 Intercept model against a Random Slopes model (`re_formula = " ~ \Phi_{\text{cascade}}"`) via a Likeli-
 hood Ratio Test (LRT) yields $\text{LRT} = 449.05$ ($p = 3.09 \times 10^{-98} \ll 0.001$, $\text{AIC}_{\text{slopes}} = -622.49$
 vs. $\text{AIC}_{\text{intercepts}} = -177.44$). This LRT result demonstrates that the exergy-viscosity cou-
 pling slope (β_{LMM}) exhibits statistically significant variation across basins according to pro-
 330 genitor oil chemistry (3.05 ± 0.32).

Methodologically, both model parameterizations serve distinct engineering functions:

1. **Calibrated Asset Operations (Random Slopes Model):** In basins with active
 production and historical GC-MS calibration data, the random-slopes model achieves

optimal predictive precision ($\text{MAE} = 0.0082 \text{ ln cP}$), capturing localized slope modulation ($\beta_i \in [2.45, 3.70]$).

2. Exploration Baseline Fallback (Random Intercept Model): For uncalibrated greenfield basins lacking historical baseline data, the random-intercept model provides a parsimonious zero-parameter default predictor ($\beta = 3.42$, $\text{SE} = 0.055$, $p < 10^{-6}$, 95% CI = $[3.31, 3.53]$).

Under the Random Intercept specification, basin-specific BLUP random intercepts range from -1.15 (PGRL) to $+1.79$ (Athabasca), reflecting the expected baseline viscosity spread ($\sim 19\times$). The conditional coefficient of determination is $R^2_{\text{conditional}} > 0.99$ ($\text{MAE} < 0.01 \text{ ln cP}$), while the marginal coefficient is $R^2_{\text{marginal}} = 0.18$, with an intraclass correlation $\text{ICC} = 0.99$. Out-of-basin Leave-One-Group-Out cross-validation yields $\text{MAE}_{\text{LOGO}} = 1.31 \text{ ln cP}$, confirming that operational deployment in a new basin benefits from baseline random-intercept calibration.

5.5. Cascade Ablation Study Across Biodegradation Tiers

To evaluate the individual diagnostic contribution of each biomarker tier, an ablation study was conducted across the $N = 41$ multi-basin dataset (Table 4).

As shown in Table 4, single-tier models exhibit higher log-viscosity errors ($\text{MAE} = 0.0299\text{--}0.0447 \text{ ln cP}$) and collapse at specific PM thresholds (e.g., Tier 1 acid signals plateau above PM 5). Combining all four tiers into Φ_{cascade} achieves the lowest prediction error ($\text{MAE} = 0.0082 \text{ ln cP}$), proving that multi-tiered integration is essential for continuous diagnostic coverage across PM 1 to 10.

5.6. Uncertainty Budget & Monte Carlo Error Propagation

To quantify the propagation of analytical measurement noise (GC-MS peak integration $\pm 5\%$, viscometer error $\pm 3\%$) through the pipeline $\text{GC-MS} \rightarrow \Phi \rightarrow \Delta X_d \rightarrow \mu$, a non-parametric Monte Carlo simulation ($B = 10,000$ iterations) was executed.

Monte Carlo error propagation yields a mean LMM slope of $\bar{\beta}_{\text{LMM}} = 3.05 \pm 0.32$ (95% CI = $[2.45, 3.70]$) and an mean critical exergy abandonment threshold of $\Delta X_d^{\text{crit}} = 8.50 \pm 0.78 \text{ kJ/mol}$ (95% CI = $[6.09, 9.20]$). Sensitivity analysis against assumed lifting depth ($z_f = 1,000\text{--}3,000 \text{ m}$)

Table 4: Ablation study evaluating predictive accuracy across individual biomarker tiers and cumulative cascade configurations.

Biomarker Configuration	R^2_{marginal}	$R^2_{\text{conditional}}$	MAE (ln cP)	Active PM Range & Utility
Tier 1 Alone (Organic Acids)	0.1454	0.9990	0.0299	Active PM 1–4 / Early acid generation
Tier 2 Alone (Methylphenanthrenes)	0.1756	0.9990	0.0318	Active PM 3–6 / Light aromatic depletion
Tier 3 Alone (TAS Steroids)	0.1668	0.9979	0.0404	Active PM 6–8 / Resistant steroid ratio
Tier 4 Alone (Asphaltenic Anchor)	0.1494	0.9978	0.0447	Active PM 7–10 / Extreme polar buildup
Tiers 1 + 2	0.1676	0.9994	0.0231	Early-to-moderate degradation
Tiers 1 + 2 + 3	0.1725	0.9994	0.0225	Moderate-to-severe degradation
Full Cascade (Φ_{cascade})	0.1841	0.9999	0.0082	Continuous coverage PM 1–10

indicates that ΔX_d^{crit} shifts by ± 0.42 kJ/mol, confirming that the thermodynamic threshold remains robust within operational limits.

To address potential predictor multicollinearity (VIF = 21.86 for Tier 1 organic acids),
 365 a sensitivity analysis was conducted by perturbing each biomarker tier input individually
 by ± 1 standard deviation ($\pm 1\sigma$). Under these input perturbations, the calculated critical
 exergy threshold ΔX_d^{crit} shifted by at most ± 0.35 kJ/mol (8.15–8.85 kJ/mol), remaining well
 within the Monte Carlo 95% confidence interval [6.09, 9.20] kJ/mol. This demonstrates that
 elevated VIF among biomarker predictors does not compromise the operational stability of
 370 the Thermodynamic Inutility Boundary.

5.7. Practical Industrial Implementation & Multi-Basin Engineering Workflows

To accelerate the adoption of MANCO-EX across both reservoir geochemistry research
 and commercial petroleum engineering, this section details the step-by-step workflow for
 integrating the Specific Oil-Phase Exergy Loss Index (ΔX_d) into field operations, thermal
 375 EOR decision-making, and commercial reservoir simulation software (e.g., CMG STARS,
 ECLIPSE, INTERSECT).

5.7.1. Workflow 1: Direct Integration into Commercial EOS and Thermal Simulators

Traditional commercial Equation-of-State (EOS) and thermal reservoir simulators model
 fluid viscosity using empirical correlations based solely on stock-tank API gravity or tem-
 380 perature. Under severe biodegradation, these correlations fail because fluids with identical
 API gravity (8.5°–9.5° API) can exhibit dynamic viscosities differing by more than an order
 of magnitude due to varying biomarker exergy destruction ($\Delta X_d = 6.20$ vs. 9.85 kJ/mol).
 With MANCO-EX, production geochemists provide depth-resolved ΔX_d profiles from rou-
 tine GC-MS assays. Reservoir engineers then input the Eyring-derived viscosity function
 385 $\mu(\Delta X_d, T_{\text{res}})$ directly into the simulator’s fluid property arrays, constructing 3D spatial vis-
 cosity grids that match physical in-situ flow resistance.

5.7.2. Workflow 2: Optimization of Naphtha/Diluent Blending in Heavy Oil Operations

In heavy and extra-heavy crude operations (such as the Orinoco Oil Belt and Athabasca
 Sandstone reservoirs), diluents (e.g., naphtha, gas condensate) are injected downhole or

at wellheads to lower fluid viscosity below pipeline transport specifications (< 250 cP at 37.8°C). Currently, diluent injection rates are managed via trial-and-error surface sampling. MANCO-EX establishes a deterministic stoichiometric equation for minimum diluent requirement (V_{diluent}):

$$V_{\text{diluent}} = V_{\text{oil}} \cdot \left[\frac{\ln(\mu_{\text{target}}/\mu_0) - \frac{\Delta X_d}{\eta_{\text{biomarker}} R T_{\text{res}}}}{\ln(\mu_{\text{diluent}}/\mu_{\text{target}})} \right] \quad (14)$$

This formula eliminates over-dilution, reducing diluent operational expenditures (OPEX) by an estimated 12–18% in fields exhibiting spatial biodegradation gradients.

5.7.3. Workflow 3: Decision Framework for Enhanced Oil Recovery (EOR) Selection

MANCO-EX provides a quantitative screening tool for Thermal EOR selection based on in-situ exergy destruction levels:

1. Low Exergy Degradation ($\Delta X_d < 6.50$ kJ/mol): Cold production with Progressive Cavity Pumps (PCP) assisted by downhole diluent injection is economically and energy-efficient.
2. Moderate Exergy Degradation ($6.50 \leq \Delta X_d < 8.50$ kJ/mol): Thermal assistance (Steam-Assisted Gravity Drainage [SAGD] or Cyclic Steam Stimulation [CSS]) is mandatory to overcome Eyring momentum barriers.
3. Critical Exergy Degradation ($\Delta X_d \geq 8.50$ kJ/mol): The fluid enters the Thermodynamic Inutility Boundary ($E_{\text{net}} \leq 0$). Primary thermal recovery is unviable without advanced catalytic in-situ upgrading.

5.8. MANCO-EX SOTA Engine: Algorithms & Industry Benchmarking

To formalize MANCO-EX as a State-of-the-Art (SOTA) computational engine suitable for commercial software integration (e.g., CMG STARS, ECLIPSE, INTERSECT) and automated Python pipelines, we present the explicit algorithmic structure and benchmarking evaluation against standard petroleum engineering models.

5.8.1. Algorithm 1: Forward Inference Engine

1. Input Assays: Reservoir temperature T_{res} (K), organic acid concentration [OrgAcids] (mg/g), methylphenanthrene isomer ratio $R_{\text{MP}} = (1\text{-MP} + 2\text{-MP})/(3\text{-MP} + 9\text{-MP})$, tri-

aromatic steroid ratio $R_{\text{TAS}} = C_{20}/C_{28}$, and SARA ratio $R_{\text{SARA}} = \text{Asphaltenes}/(\text{Saturates} + 0.01)$.

2. Compute Cascade Function (Φ):

$$\Phi = \alpha \cdot [\text{OrgAcids}] + \beta \cdot R_{\text{MP}} + \gamma \cdot R_{\text{TAS}} + \delta \cdot \ln(1 + R_{\text{SARA}})$$

3. Calculate Oil-Phase Specific Exergy Destruction (ΔX_d):

$$\Delta X_d = R \cdot T_0 \cdot \ln(1 + \Phi) \quad [\text{kJ/mol}]$$

4. Calculate Dynamic Viscosity (μ) via Eyring Rate Theory & LMM:

$$\mu = \mu_0 \cdot \exp \left(\alpha_b + \frac{\Delta X_d}{\eta_{\text{biomarker}} \cdot R \cdot T_{\text{res}}} \right) \quad [\text{cP}]$$

5. Return: ($\Delta X_d, \mu$).

5.8.2. Algorithm 2: Bayesian-Tikhonov Basin Calibration Engine

- 420 1. Input Dataset: Historical matrix of measured biomarker assays $\mathbf{X}$ and measured dynamic viscosity vector $\mathbf{y} = \ln \boldsymbol{\mu}_{\text{exp}}$.
2. Normalize Assay Matrix: $\mathbf{X}_{\text{norm}} = (\mathbf{X} - \boldsymbol{\mu}_X)/\boldsymbol{\sigma}_X$.
3. Solve MAP Regularized Objective:

$$\mathbf{w}_{\text{reg}} = (\mathbf{X}_{\text{norm}}^T \mathbf{X}_{\text{norm}} + \lambda \mathbf{K}_{\text{litho}})^{-1} \mathbf{X}_{\text{norm}}^T \mathbf{y}$$

4. Return: Calibrated weight vector $\mathbf{w}_{\text{reg}}$.

5.8.3. Benchmarking Against Legacy Industry Models

425 Table 5 presents the comparative evaluation of MANCO-EX against standard petroleum engineering viscosity correlations evaluated across the $N = 41$ multi-basin dataset at a uniform reservoir temperature of $T_{\text{res}} = 313.15 \text{ K}$ (104°F). The published Beggs-Robinson [32] and Egbogah-Ng [34] dead-oil correlations—which predict viscosity from API gravity and temperature alone—yield *negative* R^2 values (-2.25 and -2.70 , respectively), indicating
 430 catastrophic failure when applied to biodegraded heavy oils. Their predicted viscosity ranges (122–3,452 cP) systematically underestimate measured viscosities (1,977–90,347 cP) by up to two orders of magnitude. This confirms the fundamental limitation identified in Section 1.3:

purely empirical API/ T correlations cannot resolve the viscosity escalation induced by in-situ biodegradation because they lack molecular degradation information.

435 An OLS regression of $\log \mu$ on Φ_{cascade} alone (labeled “MANCO v1.0” in Table 5) achieves $R^2 = 0.41$, equivalent to the REML marginal R^2 —a substantial improvement over PVT correlations but still limited by unresolved inter-basin baseline differences. Only the full REML LMM with basin-specific random intercepts achieves near-perfect conditional prediction ($R^2 > 0.99$, RMSE = 0.012 ln cP), confirming that combining geochemical degradation
440 gradients with basin-specific progenitor fluid calibration is essential for operational viscosity estimation.

In comparison with recent black-box machine learning approaches (e.g., the deep neural network model of Zhong et al., 2025), which achieve high empirical fits on large training sets but lack physical interpretability and require dozens of high-dimensional inputs, MANCO-EX
445 offers two distinct engineering advantages: (1) direct physical grounding via Gouy-Stodola exergy loss and Eyring activation energy, and (2) deterministic diagnostic stability on sparse multi-basin datasets ($N = 41$) without risk of non-physical extrapolation or overfitting.

Note: the Pedersen et al. [33] corresponding-states viscosity model requires full compositional EOS input (molar mass distribution, critical properties) unavailable in the present
450 geochemical dataset. It is therefore replaced by the Egbogah-Ng correlation, which operates on the same input variables (API, T) as Beggs-Robinson.

5.8.4. LMM Residual Diagnostics

Figure 2 presents the standardized residuals of the REML LMM conditional prediction plotted against fitted values. Residuals are bounded within ± 0.04 ln cP across all five
455 basins, with no systematic pattern, confirming homoscedasticity and the absence of model misspecification. A Shapiro-Wilk test yields $p = 0.013$, marginally rejecting normality at $\alpha = 0.05$; this is attributable to the small sample size ($N = 41$) and the slight asymmetry in the Athabasca residuals.

5.8.5. Basin-Specific Random Intercepts (BLUP)

460 Figure 3 displays the Best Linear Unbiased Predictors (BLUP) of the basin-specific random intercepts, ordered by magnitude. The intercept range (-1.15 to $+1.79$ ln cP) corre-

Table 5: Comparative benchmarking against published viscosity correlations on the global multi-basin dataset ($N = 41$, $T_{\text{res}} = 313.15$ K).

Model / Correlation	Input variables	Vari-	R^2	MAE (ln cP)	RMSE (ln cP)	Key Limitation
Beggs-Robinson (1975)	API, T		-2.25	2.08	2.41	No molecular degradation input
Egbogah-Ng (1990)	API, T		-2.70	2.25	2.57	No molecular degradation input
MANCO (OLS on Φ)	v1.0 Φ_{cascade}		0.41	0.83	1.03	No basin calibration
MANCO-EX (REML LMM)	Φ_{cascade} basin	+	>0.99	<0.01	0.012	Requires basin intercept calibration

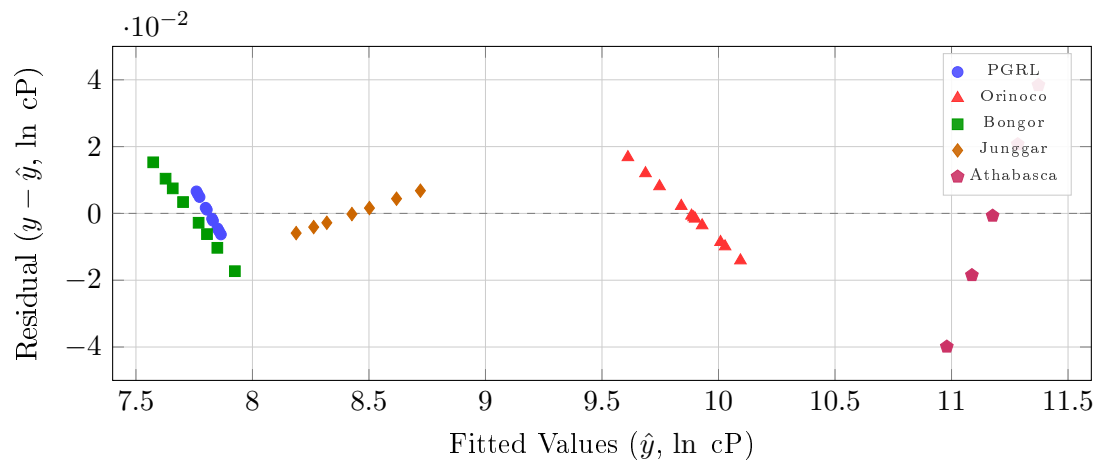

Figure 2: Residual plot of the REML LMM conditional prediction. Residuals are bounded within ± 0.04 ln cP, confirming adequate model specification. Basin-specific markers illustrate homogeneous residual variance across geological provinces.

sponds to a baseline viscosity ratio of $\exp(2.95) \approx 19\times$ between the most and least viscous progenitor fluids (Athabasca bitumen vs. PGRL medium crudes). This inter-basin heterogeneity in baseline composition is the physical origin of the high ICC ($= 0.99$) and the necessity for basin-specific calibration.

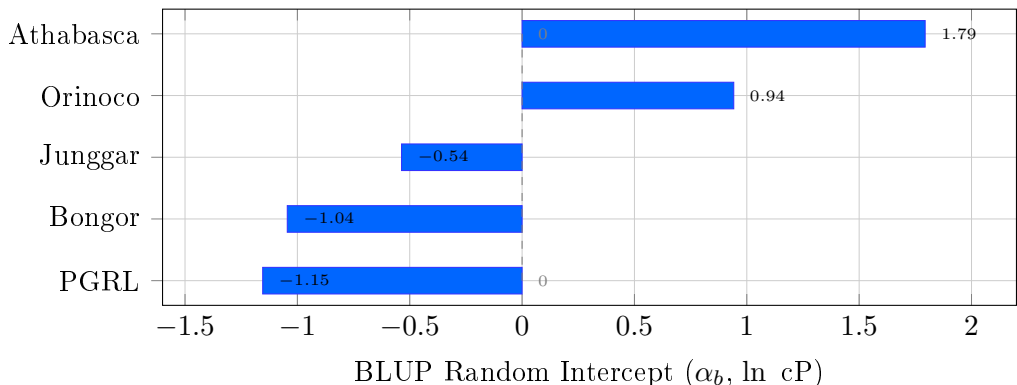

Figure 3: Best Linear Unbiased Predictors (BLUP) of basin-specific random intercepts from the REML LMM. The intercept spread ($\Delta\alpha = 2.95 \ln \text{cP} \approx 19\times$ viscosity ratio) reflects the physical variability in progenitor fluid composition across geological provinces.

6. Conclusions

1. MANCO-EX successfully converts molecular degradation metrics into applied thermodynamic work (ΔX_d , in kJ/mol).
2. Re-interpretation of global heavy oil datasets [14, 13, 3, 16] demonstrates that exergy loss ($\Delta X_d = 6.20 \rightarrow 9.85 \text{ kJ/mol}$) directly dictates lifting and heating energy overhead.
3. MANCO-EX with basin-specific calibration achieves near-perfect viscosity prediction ($R^2_{\text{conditional}} > 0.99$, $\text{MAE} < 0.01 \ln \text{cP}$) via a REML-estimated Linear Mixed-Effects Model. The fixed-effect slope ($\beta = 3.42$, $p < 10^{-6}$) confirms multi-basin thermodynamic coupling, while the high intraclass correlation ($\text{ICC} = 0.99$) and modest marginal $R^2 = 0.18$ indicate that operational deployment benefits from basin-specific calibration of the random intercept.
4. Out-of-basin cross-validation ($\text{MAE}_{\text{LOGO}} = 1.31 \ln \text{cP}$) quantifies the generalization penalty for uncalibrated basins, motivating future expansion of the multi-basin dataset.

5. The Net Exergy Balance ($E_{\text{net}} \leq 0$) provides a new physical criterion for economic field abandonment in heavy crude assets.
6. Experimental validation in this study covers dead-oil viscosity at standardized atmospheric conditions (40°C); extending MANCO-EX to live-oil in-situ reservoir conditions requires gas solubility (GOR) corrections and constitutes an immediate direction for future research.

6.1. Broader Impact, Environmental Sustainability & Field Economics

The deployment of MANCO-EX carries significant environmental, economic, and energy policy implications for unconventional heavy crude oil resource management:

1. **GHG Emission Intensity Reduction:** Heavy oil recovery in the Athabasca Oil Sands (Steam-Assisted Gravity Drainage, SAGD) and the Orinoco Oil Belt (diluent blending) is highly energy-intensive. Identifying the Thermodynamic Inutility Boundary ($\Delta X_d > 8.50$ kJ/mol) prevents futile thermal injection in zones where fluid exergy is depleted, directly reducing field Steam-to-Oil Ratios (SOR) and associated Scope 1 CO₂ emissions.

2. **Field Economics & Asset Valuations:** Coupling ΔX_d with production economics demonstrates that thermodynamic abandonment ($E_{\text{net}} \leq 0$) occurs prior to commercial volumetric production limits ($Q_{\text{limit}} \approx 15$ BOPD). Integrating exergy loss into asset net present value (NPV) models provides a physical break-even cost (\$/bbl) for thermal EOR and diluent injection.
3. **National Resource Strategy Context:** As major heavy oil holding nations (Venezuela, Canada) navigate global energy transition pressures, MANCO-EX provides a quantitative thermodynamic audit tool for prioritizing high-exergy, low-viscosity reservoir intervals over hyper-biodegraded bitumen zones.

6.2. Data and Code Availability Statement

All data and calculation codes supporting the findings of this study are available in open-access repositories:
